Abstract

Due to biomass burning and coal combustion, heavy fine particulate (PM$_{2.5}$) pollution frequently occurs in Northeast China, threatening more than 117 million people’s health. Meteorological factors have always been considered as one of the key elements influencing the accumulation and dilution of PM$_{2.5}$ pollution. However, meteorological contribution to particulate pollution in Northeast China is still of great uncertainty. By using the multiple regression method, we studied the major meteorological factors affecting the accumulation and dilution of PM$_{2.5}$ pollution based on observational data. We found that wind speed, temperature inversion, and the height of the planetary boundary layer are main factors influencing PM$_{2.5}$ pollution ($PM_{2.5} > 75$ µg/m$^3$) in major cities of Northeast China. Among them, wind speed is the key factor impacting PM$_{2.5}$ concentration in Harbin and Shenyang. Meanwhile, the height of the planetary boundary layer is the key factor of PM$_{2.5}$ pollution in Changchun. Heavy pollution ($PM_{2.5} > 150$ µg/m$^3$) in Northeast China usually occurs when the wind speed is under 20 knots, the planetary boundary layer is under 500 m and the temperature difference of the inversion layer is over 6°C. Such results imply that, to deal with PM$_{2.5}$ pollution, we should focus on not only anthropogenic emissions but also the special meteorological condition which can affect the air pollution mechanism in Northeast China.
Keywords: fine particulate (PM$_{2.5}$) pollution; multiple regression method; wind speed; temperature inversion; planetary boundary layer height

1. Introduction

Several extremely severe atmospheric haze events have occurred recently in Northeast China, a major crop straw burning region of China, with air pollution reaching up to nearly 2 to 3 times of the historical record (Chen et al. 2015; Wen et al. 2018). Fine particle matter (PM$_{2.5}$) has been proved harmful to human health and regarded as the main factor impairing visibility (He et al. 2001; Heal et al. 2012; Jung et al. 2010; Kan et al. 2012; Wang and Christopher 2003). It exerts large influences on the development of planetary boundary layer (PBL) through the positive feedback loop between aerosol and PBL (Li et al. 2017b; Lou et al. 2019; Petäjä et al. 2016) which in turn deteriorates the air quality. Besides, aerosol tends to affect the formation and development of cloud and precipitation through directly altering the radiation reaching the ground surface (Lohmann and Feichter 2001; Yang et al. 2016) or indirectly altering the structure of clouds by acting as cloud condensation nucleus (Chen et al. 2016; Guo et al. 2016; Guo et al. 2019; Twomey 1977), albeit its inconclusive effect on weather and climate systems (Fan et al. 2016; Li et al. 2019; Rosenfeld et al. 2014). In view of its potential huge influence, fine particulate pollution has attracted great attention from the Chinese government. Many regulations and standards have been made to control the fine particulate pollution (Wen et al. 2018). By adopting these measures, a gradual decrease in the PM$_{2.5}$ concentration...
over time has been witnessed recently (Wen et al. 2018). However, PM$_{2.5}$ pollution in northeastern China is still non-negligible, especially around harvest time (Chen et al. 2017).

The pollution during the heating season in Northeast China is mainly caused by evening biomass burning and coal combustion (Fang et al. 2017; Fang et al. 2001; Zhang et al. 2011). In addition, meteorological factors are important to the variation of PM$_{2.5}$ concentrations. Researches show that wind speed has a negative effect on PM$_{2.5}$ concentration (Chen et al. 2015; Chen et al. 2017; Liang et al. 2015; Wen et al. 2018). Wind speed can facilitate plume spread and dilution, leading to lower PM$_{2.5}$ concentrations. In such way, atmospheric horizontal mixing has been considered as one of the most efficient dilution mechanisms (Marcazzan et al. 2001). Studies show that lower height of the planetary boundary layer (HPBL) weakens the dispersion ability of the atmosphere (Dickerson et al. 2007; Marcazzan et al. 2001; Seinfeld et al. 2006; Wen et al. 2018; Zhang et al. 2015). HPBL, also known as the boundary layer top, refers to the thickness of the planetary boundary layer. The characteristic of the boundary layer height is that the turbulence coefficient at this height is zero and the free atmosphere is above it. The diffusion and transportation of pollutants in the lower atmosphere depends to a large extent on the boundary layer structure. Within the boundary layer, turbulence can fully mix particles and gases (Garratt 1994). In addition, the inversion layer boosts the accumulation of pollutants in the atmosphere (Fang et al. 2017; Wang et al. 2014b). Temperature inversion is a reversal of the
normal behavior of temperature in the troposphere, in which a layer of cool air at the surface is overlain by a layer of warmer air. When inversion occurs, upward movement of the lower atmosphere decreases and the pollutants are trapped in the lower atmosphere (Xu et al. 2019). In winter, the recurrent or continuous thermal inversions with fog at ground level are the major contributors to the massive amount of air pollutants accumulated in the lower layer of the atmosphere (Marcazzan et al. 2001). Moreover, haze weather can form in a faster way under high humidity conditions. Some researchers conclude that the relative humidity (RH) could well explain the daily variations of PM$_{2.5}$ (Fang et al. 2017; Ma et al. 2017; Sun et al. 2013). Previous studies indicated that the synoptic scale meteorological conditions and multiple meteorological factors can have a complicated impact to the PM$_{2.5}$ pollution (Chen et al. 2018; Liu et al. 2018; Miao et al. 2017; Wang et al. 2014a).

Three typical large cities of northeast China (i.e., Harbin, Changchun, and Shenyang) were studied in this research, using statistical data and regression model analysis, to investigate the impact of different meteorological factors on major cities in Northeast China. The study result of this research is of great benefit to making suitable and effective strategies for PM$_{2.5}$ control in Northeast China.
2. Data and Methods

2.1 Study Area

As shown in FIG. 1, Northeast China is covered mostly by plain. The northeast plain is surrounded by mountains, alluvial plains and terraces, with an elevation of about 200 meters. The northeast plain is located in a temperate and warm temperate zone with continental monsoon climate characteristics. Significant seasonal differences exist in this area. The summer is short, warm and rainy. Meanwhile the winter is long, cold, and snowy. And the monsoon alternates between winter and summer.

Figure 1. Map of the study area. (a) shows the topographic map of China and the location of...
Northeast China. (b) shows the topographic map of Northeast China and the location of Shenyang, Changchun, and Harbin. (c), (d) and (e) gives the location of PM2.5 studying sites in Shenyang, Changchun, and Harbin respectively.

Considering their meteorological conditions and urban development status, three typical large cities in Northeast China were selected in this study to reflect the major characteristics of PM$_{2.5}$ pollution in Northeast China. Among the three cities, Harbin, the capital of Heilongjiang Province, is located in the highest latitude area, having the lowest temperature, with a flat terrain. Over 10.9 million people live in Harbin. The southeastern part of Harbin is located in the hills, meanwhile, mountainous area occupied the north part. The Songhua River flows through the middle part of Harbin. Changchun is located in the middle part of Northeast China with over 7.5 million people. The Changchun area, apart from a small area of low hills in the east, is mostly comprised of terraces. The terrain of Changchun is flat and convenient for transportation (Fang et al. 2001). In Changchun, from November to March, coal burning phenomenon for heating purpose is widespread. The heating area is scattered in one-fourth of the city area (Fang et al. 2001). Shenyang, the largest city in the Northeast China, has over 8.3 million people (Han et al. 2010; Xu et al. 2000). It is located in the southeastern part of Northeast China, mainly in the plains, with mountains and hills concentrated in the southeast. Shenyang shows similar meteorological characteristics with the other two cities mentioned above: a monsoon-influenced humid continental climate, which has monsoon-caused hot,
humid summers and dry, cold winters driven by the Siberian anticyclone (Han et al. 2010).

2.2 Data Source and Treatment

The time period of the studied PM$_{2.5}$ data ranges from 2015 to 2017, provided by the China Meteorological Administration. The continuous hourly PM$_{2.5}$ concentration data has been monitored by the 33 stations: 12 sites in Harbin, 10 sites in Changchun, and 11 sites in Shenyang. As can be seen in FIG. 1, the sites are evenly distributed throughout the cities. Thus the hourly average value of these sites can reasonably represent the PM$_{2.5}$ concentration of the three cities. To keep consistency with the meteorological data, the PM$_{2.5}$ concentration was calculated at 8:00 a.m. and 8:00 p.m.

The PM$_{2.5}$ data is classified into three states: the non-pollution state (PM$_{2.5}$ $\leq$ 75 µg/m$^3$), pollution state (PM$_{2.5}$ $>$ 75 µg/m$^3$), and heavy pollution state (PM$_{2.5}$ $>$ 150 µg/m$^3$) (Ma et al. 2017; Tian et al. 2017).

Meteorological data comes from the radiosonde measurements provided by the Integrated Global Radiosonde Archive developed by the American National Climatic Data Center (NCDC) (Durre et al. 2006). The humidity data and wind data are extracted specifically with wind velocity and wind direction at 850 hPa. In general, temperature drops as the altitude increases, beneficial to the convective phenomenon which accelerates the pollutants in the lower layer moving and diffusing upward.
However, when temperature inversion occurs, the upward movement of the lower atmosphere is weakened, causing the accumulation of atmospheric pollutants in the lower layer. Temperature inversion phenomenon can be detected by the temperature profile of the atmosphere. Two factors, namely the temperature difference of the inversion layer (TI_T) and the depth of the inversion layer (TI_D), are used to describe the intensity of temperature inversion. In this research, the two factors of the inversion layer is derived from the Integrated Global Radiosonde Archive (IGRA) soundings data. We first analyze the temperature data for different air layers and find if there exist a temperature sequence segmentation in the profile that has monotonic increasing trend with the increase of the layer heights. If exist, the temperature inversion is defined. Then the temperature difference is calculated by subtracting the temperatures at the top and bottom of the inversion layers. And the depth of the inversion layer is calculated by subtracting the heights at the top and bottom of the inversion layers.

HPBL data used in this research is provided by National Centers for Environmental Prediction (NCEP) and Final (FNL) Reanalysis data. It is collected at 06:00 and 18:00 UTC. The HPBL data is a grid dataset and the horizontal resolution of HPBL is $1 \times 1^\circ$ (Zang et al. 2017). In this research, the HPBL values of Harbin, Changchun and Shenyang are calculated using the inverse distance weighting method based on the values in four closest grid points.
2.3 Methods

In order to decouple the contribution of different meteorological factors, a multiple regression model was used to analyze the correlations between PM$_{2.5}$ concentration and meteorological factors. Based on atmospheric dispersion equations, the particulate concentration is correlated with meteorological parameters in multiplicative form other than additive form (Chaloulakou et al. 2003; Gu et al. 2018; Hien et al. 2002). The multiple regression analysis model can be constructed as follows:

\[ B = k \cdot f(\tau_n) \]  (1)

where \( B \) represents the monitored PM$_{2.5}$ concentration, \( k \) represents autochthonic contribution to PM$_{2.5}$. \( k \) is considered to remain unchanged during each season. \( f(\tau_n) \) represents the meteorological impact on PM$_{2.5}$. Furthermore, the regression model can be expressed as follows:

\[ B = k \prod (P_i)^{\alpha_i} \]  (2)

The exponent \( \alpha_i \) represents the response of particulate concentration \( B \) to the rate of change in meteorological parameter \( P_i \). \( f(\tau_n) \) was calculated using five meteorological factors (Pi) in this model: wind velocity (WV), HPBL, TI_T, TI_D and RH. As a result, the model can be expressed as follows:

\[ B = k \cdot (WV)^{\alpha_1} \cdot (HPBL)^{\alpha_2} \cdot (TI_T)^{\alpha_3} \cdot (TI_D)^{\alpha_4} \cdot (RH)^{\alpha_5} \]  (3)

Then, take the logarithm for both sides of this equation. Eq.(3) can be further transformed to a multiple linear regression model:

\[ \ln B = \ln k + \sum \alpha_i \ln (P_i) + \varepsilon \]  (4)
where $\ln k$, $\alpha_i$ and $\epsilon$ represent the intercept, regression coefficients, and the error term respectively. WV, RH, TI_T, TI_D, and HPBL were selected in this research as the studied meteorological parameters which influence the PM$_{2.5}$ concentration characteristics in Northeast China. To find the determinant(s) of the PM$_{2.5}$ concentrations among various indicators, the data were analyzed by a stepwise multiple regression method with a significance level of 95% ($p=0.05$) set for the regression coefficients.

The regression coefficient $\alpha_i$ can only represent the positive or negative relationship between the PM$_{2.5}$ concentration and the meteorological factors. To find the most important factors that impact the PM$_{2.5}$ concentration in different cities of Northeast China, we calculated the standardized coefficient of the regression model. The standardized coefficient can compare the relative importance of different kinds of factors to the PM$_{2.5}$ concentration. The bigger the absolute value is, the more important the meteorological factor will be. (Newman and Browner 1991).

3. Result and Discussion

3.1 Variation of the PM$_{2.5}$ Concentrations Correlated with Different Meteorological Factors

Massive biomass burning and coal consumption together with meteorological conditions potentially cause the high level of PM$_{2.5}$ pollution in Northeast China’s
winter (Han et al. 2010; Segura et al. 2013). Studies show that PM$_{2.5}$ pollution in Northeast China originates from anthropogenic activities, such as straw burning and coal combustion for both industrial and domestic purpose (Guan et al. 2018; Zhang et al. 2010). Meanwhile, individual meteorological factors such as relative humidity, wind speed and temperature inversion have non-negligible impacts on local PM$_{2.5}$ concentrations (Cheng and Lam 1998; Ruellan and Cachier 2001; Wen et al. 2018). The distribution and variation of the source of pollution are usually stable during each season. However, the dilution and accumulation abilities impacted by the meteorological conditions can change significantly. Investigating the impacts of meteorological factors is beneficial to a better understanding of the variations of PM$_{2.5}$ mass concentrations.

As shown in FIG. 2, the correlation between PM$_{2.5}$ concentration and wind direction and speed were similar in the three cities. PM$_{2.5}$ concentration is negatively associated with wind speed (Chen et al. 2017; Wen et al. 2018). High PM$_{2.5}$ concentration tends to appear in a low wind speed situation. In Harbin, Changchun, and Shenyang, 79.2%, 79.1%, and 80.4% of the heavy PM$_{2.5}$ pollution (PM$_{2.5}$ > 150 µg/m$^3$) occurs in the days when the wind speed is less than 20 knots (a knot is a unit typically used to indicate wind speed, and thus used in this research. 1 knot = 1.852 km/hour). Biomass burning in spring and autumn and coal combustion for domestic heating in winter produce a great deal of air pollutants (Bao et al. 2015; Zhang et al. 2010). Higher wind speed is likely to promote the spread of pollutant, which is beneficial for the
dilution of PM$_{2.5}$ pollutants (Wen et al. 2018). The westerly wind prevails during pollution days in Northeast China. In Harbin, over 70% of pollution days (PM$_{2.5}>75$ µg/m$^3$) are related with the wind which has a direction between 240-330°. As for Changchun and Shenyang, the dominant wind direction in pollution days is concentrated at 210-330°. In general, Harbin, Changchun, and Shenyang are mainly dominated by the southwest wind during the whole year, meanwhile the northwest wind is the prevailing wind in winter.

As shown in FIG. 3, in terms of statistics, there is a general negative correlation
between HPBL and PM$_{2.5}$ concentrations for Harbin, Changchun, and Shenyang. Heavy PM$_{2.5}$ pollution (PM$_{2.5}$$>$150 µg/m$^3$) usually occurs in the lower HPBL (<500 m). HPBL plays a vital role in the variation of PM$_{2.5}$ concentration. The barrier effect at the top of the planetary boundary layer (PBL) hinders air pollutants from being transported to the free troposphere, so that aerosol particles are constrained in the PBL (Li et al. 2017a; You et al. 2015). Lower HPBL is usually related with higher concentrations of PM$_{2.5}$, and higher HPBL is usually associated with smaller ground-level PM$_{2.5}$ concentration as a result of large vertical mixing ability (Yao et al. 2012).

Figure 3. Correlation between PM$_{2.5}$ and the height of the planetary boundary layer in Harbin, Changchun, and Shenyang for (a): pollution days (>75 µg/m$^3$) and (b): non-pollution days (<=75 µg/m$^3$).

As can be seen in FIG. 4, PM$_{2.5}$ concentration is significantly and positively correlated with the intensity of temperature inversion which is described by TI_T and TI_D. In Harbin, Changchun, and Shenyang, 60.6, 44.8, and 56.9% of PM$_{2.5}$ pollution days occur with temperature inversion phenomenon, respectively. Only 14.4, 18.4,
and 15.4% of PM2.5 pollution days have no temperate inversion. PM2.5 concentration rises significantly when TI_T is greater than 6°C in Harbin and Changchun. However, the relationship between TI_T and PM2.5 in Shenyang is not so significant in pollution days. The TI_D in Shenyang is generally thicker than that of other two cities. Heavy pollution usually occurs when TI_D is bigger than 600 m in Harbin and Shenyang. Compared to summer, the inversion layer in winter is thicker and has a longer duration. The atmosphere remains static once temperature inversion occurs. In static atmosphere, air pollutants are not easily dispersed vertically and, thus, accumulated near the surface. Additionally, a large temperature difference within a thin inversion layer can also cause high concentrations of PM2.5 in the ground layer.

Figure 4. Statistics of PM2.5 concentrations with temperature inversion. Variation of the PM2.5
concentrations correlated with the temperature difference of the inversion layer (TI_T) during (a): pollution days (>75 µg/m³) and (b): non-pollution days (<=75 µg/m³). Variation of the PM2.5 concentrations correlated with the depth of temperature inversion (TI_D) during (c): pollution days (>75 µg/m³) and (d): non-pollution days (<=75 µg/m³).

As can be seen in FIG. 5, the relationship between RH and PM2.5 in Northeast China is not as significant as other air pollution areas. There is even a negative correlation between PM2.5 and RH. Possible reasons are that rainy and snowy weather accompanied with moist air can deposit the particulate pollutants so that air becomes clear, and when the air pollution is caused by the dust particles, the moisture in the air remains constant low (Sun et al. 2013).

Figure 5. Variation of the PM2.5 concentrations correlated with different RH condition during (a): pollution days (>75 µg/m³) and (b): non-pollution days (<=75 µg/m³) in Harbin, Changchun, and Shenyang respectively. The RH is divided into 5 segments (i.e. 0-20, 20-40, 40-60, 60-80, and 80-100).
3.2 Quantitative Multiple Regression Analysis between \( PM_{2.5} \) Concentration and Meteorological Factors

PM\(_{2.5}\) concentration has dropped continuously during the past three years in Northeast China. However, daily PM\(_{2.5}\) levels varied remarkably, rising and falling rapidly with alternating sharp peaks and deep troughs (Wen et al. 2018). In Table 1, the confidence coefficient for meteorological factors at 95% confidence level (p-value<0.05) indicates the factors significantly impact the daily variation of PM\(_{2.5}\) concentration to some extent. Wind speed, HPBL, and temperature inversion are important meteorological factors affecting the PM\(_{2.5}\) pollution in Northeast China. During pollution days, the regression coefficients of wind speed and HPBL are negative values, which show a clear negative influence of wind speed and HPBL on fine particle concentrations. Meanwhile, the values for the coefficients of TI_T and TI_D are positive, which indicates that temperature inversion has a positive impact on the accumulation of PM\(_{2.5}\). A meteorological factor plays the dominant role in affecting PM\(_{2.5}\) pollution when its standardized coefficient has the biggest absolute value. By comparing the standardized coefficients of different factors in the regression model, the most important factors are concluded. Wind speed is the key meteorological factor impacting PM\(_{2.5}\) concentrations in Harbin and Shenyang. Meanwhile, HPBL is the key factor in Changchun.

Straw burning and pollutant emission, near-surface temperature inversion, static wind and together with other extreme meteorological conditions contribute to the PM2.5
pollution, especially in autumn and winter. Breezeless wind hinders the dispersion and transport of the atmospheric pollutants released by straw burning. On the contrary, high wind speed is beneficial to the horizontal dilution of the pollutants. On the other hand, the turbulence is strengthened with the increase of wind speed, which is also beneficial to the pollutant dilution and spreading. There are significant differences between the situations with and without the existence of temperature inversion. Temperature inversion decreases the upward movement of the lower atmosphere and causes the pollutants trapped in the lower atmosphere. Frequent atmosphere conditions with temperature inversion in winter can cause the accumulation of atmospheric particles (Han et al. 2010; He et al. 2001). The convection between upper and lower layers decreases, so that the atmospheric pollutants in the near-surface layer can hardly be transported upward. At the same time, the pollutants never stop accumulating, which exacerbates air pollution. The diffusion and transportation of pollutants in the lower atmosphere depends to a large extent on the boundary layer structure. Within the boundary layer, turbulence can fully mix particles and gases. All the three factors have significant influence on the PM$_{2.5}$ concentrations in Northeast China. As can be seen in the multiple regression result (Table 1), during pollution days, all the three cities have the wind speed as one of the major impact factors. However, different from other two cities, the temperature inversion is not a major impact factor for Changchun. Such result may be caused by the fact that the altitude of Changchun (236.8 m) is higher than Harbin (171.7 m) and Shenyang (41.6 m). And the temperature inversion has the characteristic that it occurs more obviously in the
lowland (or valley) area than the highland area.

As can be seen from Table 2, during non-pollution days, HPBL and temperature inversion are important factors affecting PM$_{2.5}$ in Harbin and Changchun. In Shenyang, TI_D is the only important determinant impacting PM$_{2.5}$ concentration. In summer, the thickened mixing layer improves the dispersion of pollutants in the atmosphere. In winter, frequent and persistent thermal inversions at ground level drive considerable amount of air pollutants to accumulate in the lower layer of the atmosphere (Marcazzan et al. 2001). Although wind speed, HPBL, and TI_T are important factors of PM$_{2.5}$ concentration, their correlations with PM$_{2.5}$ concentration during non-pollution days are not significant.

FIG. 6 shows the occurrence of PM$_{2.5}$ pollution and non-pollution days in different meteorological conditions from 2015 to 2017. The meteorological factors for different cities are selected based on the significance level of 95% in Table 1. For Harbin, HPBL, WV, and TI_T are major impact factors. PM$_{2.5}$ pollution usually occurs, with a possibility of 91.6%, when the wind speed is under 20 knots, HPBL is lower than 1500 m and TI_T is higher than 8°C. On the contrary, the possibility of occurrence of PM$_{2.5}$ pollution is only 27.2% for the whole year. For Changchun, PM$_{2.5}$ pollution is majorly impacted by wind speed and HPBL, the possibility is 61.7% when the wind speed is under 20 knots and HPBL is lower than 600 m. Meanwhile, the possibility is only 22.7% for the whole year. As for Shenyang, the possibility of the occurrence of PM$_{2.5}$ pollution rises from 24.9% to 70.3% when the wind speed is under 20 knots, and TI_D is greater than 775 m.

Figure 6. The occurrence of PM$_{2.5}$ pollution and non-pollution days in different meteorological conditions from 2015 to 2017 in Harbin (a), Changchun (b), and Shenyang (c).

4. Conclusions

To explore the impact of meteorological conditions on PM$_{2.5}$ pollution in Northeast China, we used a regression method relying on long-term ground-based PM$_{2.5}$ data.
and meteorological sounding measurements. We found that wind speed, HPBL and temperature inversion were the important meteorological factors impacting fine particulate pollution in Northeast China. Wind speed is the key factor correlated to \( \text{PM}_{2.5} \) concentration in Harbin and Shenyang, meanwhile HPBL is the key factor of \( \text{PM}_{2.5} \) pollution in Changchun. Analysis of meteorological data shows a significant negative influence of wind speed and HPBL on fine particle concentrations. Temperature inversion, which is described by TI_T and TI_D, is positively related with \( \text{PM}_{2.5} \) concentration.

In Harbin, \( \text{PM}_{2.5} \) pollution usually occurs when the wind speed is under 20 knots, HPBL is lower than 1500 m, and TI_T is higher than 8°C with a possibility of 91.6%. In Changchun, there is 61.7% possibility that \( \text{PM}_{2.5} \) pollution will happen when the wind speed is under 20 knots and HPBL is lower than 600 m. As for Shenyang, the possibility of the occurrence of \( \text{PM}_{2.5} \) pollution is 70.3% when the wind speed is under 20 knots, and TI_D is greater than 775 m. Different from other typical pollution areas, the variation of \( \text{PM}_{2.5} \) concentration during pollution days in Northeast China depends little on RH.

Apart from anthropogenic emission contribution, ambient meteorological conditions also play an important role in \( \text{PM}_{2.5} \) pollutions in Northeast China. Our results imply that, aside from local emission control, in order to achieve effective and economical air pollution governance in Northeast China, more attentions should be paid to the
impact of ambient meteorological conditions. For example, when the temperature
inversion occurs, the reduction of the coal and petroleum consuming should be
considered to prevent potential heavy air pollution situation.

This research give a preliminary study of the major meteorological factors affecting
the accumulation and dilution of PM$_{2.5}$ pollution. More meteorological factors could
be considered and the study period could to be expanded in future studies. Moreover,
this research uses the nighttime HPBL data which is usually dominated by residue
layer. The relevancy between PM$_{2.5}$ and HPBL may not be true in nighttime
sometimes. These issues can be further considered in the future work.

5. Acknowledgements

This work is supported by the National Key Research and Development Program of
China (2017YFC0212302). We would like to thank the Ministry of Environmental
Protection of China for providing the PM$_{2.5}$ observation data
(http://106.37.208.233:20035/) used in this study. We highly appreciate the National
Oceanic and Atmospheric Administration (NOAA) as well as the Integrated Global
Radiosonde Archive (IGRA) for giving us access to the historical radiosonde data.
We would also like to show great gratitude to the National Center for Atmosphere
Research (NCAR), associated with the University Corporation for Atmospheric
Research (UCAR), for the generous provision of HPBL data. Without these
institutions the experiments could not be conducted.
